Abstract

We compute the hadronic light-by-light scattering contributions to the muon anomalous magnetic moment, $a_\mu^{LL}(\text{had})$, in chiral perturbation theory that are enhanced by large logarithms and a factor of N_C . They depend on a low-energy constant entering pseudoscalar meson decay into a charged lepton pair. The uncertainty introduced by this constant is $\pm 60 \times 10^{-11}$, which is comparable in magnitude to the present uncertainty entering the leading-order vacuum polarization contributions to the anomalous moment. It may be reduced to some extent through an improved measurement of the $\pi^0 \rightarrow e^+e^-$ branching ratio. However, the dependence of $a_\mu^{LL}(\text{had})$ on non-logarithmically enhanced effects cannot be constrained except through the measurement of the anomalous moment itself. The extraction of information on new physics would require a future experimental value for the anomalous moment differing significantly from the 2001 result reported by the E821 collaboration.

The recently reported measurement of the muon anomalous magnetic moment a_μ by the E821 collaboration [1] has generated considerable excitement about possible evidence for new physics. The interpretation of the result, however, depends in part on a reliable treatment of hadronic contributions to a_μ which arise at two- and three-loop order. While the vacuum polarization contribution can be constrained by e^+e^- experiments and τ decays and appears to be under adequate theoretical control [2], recent analysis [3,4] of the hadronic light-by-light scattering contribution $a_\mu^{LL}(\text{had})$ have uncovered a sign error in previous calculations [5–9] of the dominant, pseudoscalar pole term. The resulting sign change reduces the 2.6σ deviation of a_μ from the Standard Model prediction reported in [1] by one standard deviation, thereby modifying considerably the original interpretation of the result [10,11].

The commonly quoted values for $a_\mu^{LL}(\text{had})$ (after incorporating the corrected overall sign) rely on model treatments of the off shell $\pi^0\gamma^*\gamma^*$, $\eta\gamma^*\gamma^*$ and $\eta'\gamma^*\gamma^*$ interactions. While the amplitude for pseudoscalar decay into two real photons is dictated by the chiral anomaly, the off-shell amplitudes relevant for $a_\mu^{LL}(\text{had})$ are affected by non-perturbative strong interactions whose effects cannot yet be computed with sufficient precision from first principles in QCD. Similarly, the contributions from other hadronic intermediate states besides the π^0 , η , and η' cannot be computed reliably at present. The analysis of $a_\mu^{LL}(\text{had})$ falls naturally under the purview of chiral perturbation theory (χ PT), which provides systematic, model-independent framework for parameterizing presently incalculable hadronic effects. The static quantity $a_\mu^{LL}(\text{had})$ has an expansion in powers of p/Λ , where p is a small mass of order m_μ or m_π and Λ is a hadronic scale, typically taken to be $\sim 4\pi F_\pi \sim 1\text{GeV}^1$. The coefficients appearing in the expansion depend in part on *a priori* unknown “low-energy constants” (LEC’s), which parameterize the effects of non-perturbative short distance physics. In principle, the LEC’s may be determined from an appropriate set of experimental measurements.

In this Letter, we perform a χ PT calculation of $a_\mu^{LL}(\text{had})$ including all the logarithmically enhanced contributions to $a_\mu^{LL}(\text{had})$ that arise at order $N_C\alpha^3 p^2/\Lambda^2$, where N_C is the number of quark colors. We identify the dependence of $a_\mu^{LL}(\text{had})$ on the large logarithms of Λ/p as well as on the relevant LEC’s. The result for the large $\ln^2$ term – which is determined entirely by gauge-invariance and the chiral anomaly – was first given in Ref. [4] and was used to uncover the sign error in previous model calculations. However, only part of the large $\ln$ term is fixed by symmetry considerations. It receives an additional contribution involving χ , a LEC entering the rate for pseudoscalar decay into leptons. The χ -dependent piece was also computed in Ref. [4]. An analytic calculation of the χ -independent large $\ln$ term was performed by the authors of Ref. [12], who used a model for the off-shell $P\gamma^*\gamma^*$ form factor to regulate the two-loop amplitude and assumed m_μ was almost equal to m_π . The results of the latter calculation also contain a model prediction for the non-logarithmic $\mathcal{O}(N_C\alpha^3 p^2/\Lambda^2)$ contribution to $a_\mu^{LL}(\text{had})$.

In what follows, we carry out a consistent χ PT treatment of $a_\mu^{LL}(\text{had})$, providing the first complete, model-independent analysis of the terms enhanced by large logarithms through $\mathcal{O}(N_C\alpha^3 p^2/\Lambda^2)$. The sum of these terms is known, since existing measurements for $\eta \rightarrow \mu^+\mu^-$ and $\pi^0 \rightarrow e^+e^-$ branching ratios fix the value of χ . However, the uncertainty in $a_\mu^{LL}(\text{had})$ from the error in χ is significant: $\pm 60 \times 10^{-11}$, which is roughly the same size as

¹We treat m_μ and m_π to be of the same order and take both to be small compared with Λ .

the present theoretical uncertainty in the leading-order vacuum polarization contributions to a_μ . In principle, an improved measurement of the $\pi^0 \rightarrow e^+e^-$ branching ratio could reduce this source of uncertainty.

A more serious consideration involves the contributions to $a_\mu^{LL}(\text{had})$ that are beyond the order at which we compute. These include effects of order $\mathcal{O}(\alpha^3 p^2/\Lambda^2)$ which are not enhanced by a factor of N_C and order $\mathcal{O}(N_C \alpha^3 p^2/\Lambda^2)$ terms that are not enhanced by large logarithms. We parameterize all these effects in terms of $\tilde{C}$. For simplicity we will refer to $\tilde{C}$ as a low energy constant even though it has nonanalytic dependence on the quark masses. At present, $\tilde{C}$ cannot be determined in a model-independent way without reliance on the measurement of a_μ itself. Even the sign of the $\tilde{C}$ -dependent term cannot presently be fixed in an model-independent manner. The presence of this LEC renders the interpretation of a_μ in terms of new physics problematic, since the size of the $\tilde{C}$ -dependent contribution could be as large as the present experimental error in a_μ [1]. Below we discuss the conditions under which one might still be able to extract information on new physics from an a_μ measurement.

To leading order in N_C , the lowest-order chiral contributions to $a_\mu^{LL}(\text{had})$, enhanced by large logarithms, arise from the two- and one-loop graphs of Fig 1. Taking m_π and m_μ as being of $\mathcal{O}(p)$, the leading, large logarithmic contributions arise at order $N_C \alpha^3 p^2/\Lambda^2$. The two-loop graphs (Fig. 1a) contain an overall, superficial cubic divergence as well as a linearly-divergent one-loop subgraph involving two photons and a muon line. The latter must be regulated by adding the appropriate one-loop counterterm (ct) (Fig. 1b). The one-loop graphs also contain an insertion of $\chi(\mu)$. The sum of these graphs contains a residual divergence, which must be removed by the appropriate magnetic moment ct (Fig. 1c). Associated with this ct is a finite piece which, as discussed above, can only be fixed in a model-independent way by the measurement of a_μ itself. Additional contributions also arise from the graphs such as those appearing in Fig. 2. Although subdominant in N_C counting the contribution of the charged pion loop in 2b (and related diagrams) is leading order in p/Λ . The order $\mathcal{O}(\alpha^3 N_C^0)$ term arising from the three loop graphs with a charged pion loop – which we denote by $a_\mu^{LL}(\text{had})_{\text{l.o.}}$ – has been computed in Ref. [15,5]. The result is finite and contains no large logarithms. We will include this contribution when we compare the theoretical prediction for $a_\mu^{LL}(\text{had})$ with experiment.

At order $\alpha^3 p^2/\Lambda^2$ there will be contributions to $a_\mu^{LL}(\text{had})$ from higher dimension operators inserted at the vertices in the charged pion loop graph of Fig.2 and from four-loop graphs containing an additional hadronic loop. Some of these should contain large logarithms. However, these are suppressed by a factor of N_c compared to the logarithmically enhanced pieces that we compute. As remarked earlier we absorb these and many other subdominant contributions (*e.g.*, Fig. 2a) into $\tilde{C}$ and do not discuss them further here.

As inputs for amplitudes of Fig. 1, we require the Wess-Zumino-Witten $P\gamma\gamma$ interaction Lagrangian [13]:

$$\mathcal{L}_{WZW} = \frac{\alpha N_C}{24\pi F_\pi} \epsilon_{\mu\nu\alpha\beta} F^{\mu\nu} F^{\alpha\beta} \left(\pi^0 + \frac{1}{\sqrt{3}} \eta \right) + \dots \quad (1)$$

as well as the leading-order operator contributing to the decays $P \rightarrow \ell^+ \ell^-$ [14]:

$$\mathcal{L}_{P\ell^+\ell^-} = \frac{i3N_C\alpha^2}{96\pi^2} \bar{\mu} \gamma^\lambda \gamma_5 \mu \left[\chi_1 \text{Tr} \left(Q^2 \Sigma^\dagger D_\lambda \Sigma - Q^2 D_\lambda \Sigma^\dagger \Sigma \right) \right] \quad (2)$$

$$\begin{aligned}
& +\chi_2 \text{Tr} \left(Q \Sigma^\dagger Q D_\lambda \Sigma - Q D_\lambda \Sigma^\dagger Q \Sigma \right) \\
& = -\frac{N_C \alpha^2}{48\pi^2 F_\pi} (\chi_1 + \chi_2) \bar{\mu} \gamma^\lambda \gamma_5 \mu \left(\partial_\lambda \pi^0 + \frac{1}{\sqrt{3}} \partial_\lambda \eta \right) + \dots \quad .
\end{aligned} \tag{3}$$

where

$$\Sigma = \exp \left(\sum \lambda^a \pi^a / F_\pi \right) \tag{4}$$

Here, $F_\pi = 92.4$ MeV is the pion decay constant, λ^a denote the Gell-Mann SU(3) matrices, and D_λ is the covariant derivative. Note that in contrast to the conventions of Ref. [14], we have made the N_C -dependence of the LEC's χ_i explicit for the sake of clarity.

In computing the loop amplitudes involving these operators, it is important to employ a regulator which maintains the consistent power-counting of the chiral expansion. To that end, we employ dimensional regularization, where we continue only momenta (and not Dirac matrices) into $d = 4 - 2\epsilon$ dimensions. The relation between bare and renormalized couplings is,

$$\chi_1^0 + \chi_2^0 = \chi_1 + \chi_2 - \frac{6}{\epsilon} \equiv \chi(\mu) - \frac{6}{\epsilon} \quad . \tag{5}$$

Using Eq. (5) and adding the amplitudes for Fig. 1a,b, we obtain the divergent part of the two-loop amplitude

$$\mathcal{M} = -e \left(\frac{\alpha}{\pi} \right)^3 \left(\frac{N_C}{3} \right)^2 \left(\frac{m_\mu}{F_\pi} \right)^2 \left(\frac{1}{32\pi^2} \right) \left[\frac{3}{2\epsilon^2} - \left(\frac{\chi(\mu)}{2} + \frac{3}{4} \right) \frac{1}{\epsilon} \right] \bar{u} \frac{i\sigma_{\alpha\beta} q^\alpha \varepsilon^\beta}{2m_\mu} u \quad , \tag{6}$$

where q^α and ε^β are the photon momentum and polarization, respectively. We remove this divergence using a magnetic moment counterterm. The bare coupling C_0 and renormalized coupling $C(\mu)$ are related by

$$\mathcal{M}_0 = e \left(\frac{\alpha}{\pi} \right)^3 \left(\frac{N_C}{3} \right)^2 \left(\frac{m_\mu}{F_\pi} \right)^2 \left(\frac{1}{32\pi^2} \right) C_0 \bar{u} \frac{i\sigma_{\alpha\beta} q^\alpha \varepsilon^\beta}{2m_\mu} u \tag{7}$$

$$C_0 = C(\mu) + \left[\frac{3}{2\epsilon^2} - \left(\frac{\chi(\mu)}{2} + \frac{3}{4} \right) \frac{1}{\epsilon} \right] \quad . \tag{8}$$

The light-by-light contribution to the anomalous magnetic moment $a_\mu^{LL}(\text{had})$ is a physical quantity and has no dependence on the subtraction point μ . The μ -dependence of the diagrams cancels that of the couplings $C(\mu)$ and $\chi(\mu)$. To obtain the μ -dependence of the couplings we require that the bare Green's functions corresponding to the sum of Figs. 1a-c and the to the $P\ell^+\ell^-$ one-loop subgraphs, respectively, be independent of the subtraction scale. Doing so leads to a coupled set of renormalization group equations for $\chi(\mu)$ and $C(\mu)$:

$$\mu \frac{d\chi}{d\mu} = -12 \tag{9}$$

$$\mu \frac{dC}{d\mu} = -3 - \chi \quad . \tag{10}$$

The solution is

$$\chi(\mu) = 12 \ln(\mu_0/\mu) + \chi(\mu_0) \quad (11)$$

$$C(\mu) = 6 \ln^2(\mu_0/\mu) + [\chi(\mu_0) + 3] \ln(\mu_0/\mu) + C(\mu_0) \quad (12)$$

At a scale $\mu_0 = \Lambda \sim 1$ GeV, the constants $C(\mu_0)$ and $\chi(\mu_0)$ contain no large logarithms of the form $\ln^k(\Lambda/p)$ ($k = 1, 2$) where p is around m_μ or m_π . For μ of $\mathcal{O}(p)$, however, the Feynman diagrams contain no such large logarithms, and they live entirely in $C(\mu)$ and $\chi(\mu)$. Hence, the resulting expression for $a_\mu^{LL}(\text{had})$ is, in the $\overline{MS}$ scheme,

$$a_\mu^{LL}(\text{had}) = a_\mu^{LL}(\text{had})_{\text{l.o.}} + \frac{3}{16} \left(\frac{\alpha}{\pi}\right)^3 \left(\frac{m_\mu}{F_\pi}\right)^2 \left(\frac{N_C}{3\pi}\right)^2 \left\{ \ln^2\left(\frac{\Lambda}{\mu}\right) + \left[-f(r) + \frac{1}{2} + \frac{1}{6}\chi(\Lambda)\right] \ln\left(\frac{\Lambda}{\mu}\right) + \tilde{C} \right\}, \quad (13)$$

where μ is of order p and could be set equal to either m_μ or m_π . Recall that $\Lambda \sim 4\pi F_\pi \sim 1$ GeV. The function $f(r)$, with $r = m_\pi^2/m_\mu^2$, arises from the one loop diagram with a coupling proportional to $\chi(\mu)$ (Fig. 1b) and is given by²

$$f(r) = \ln\left(\frac{m_\mu^2}{\mu^2}\right) + \frac{1}{6}r^2 \ln r - \frac{1}{6}(2r + 13) + \frac{1}{3}(2 + r)\sqrt{r(4 - r)} \cos^{-1}\left(\frac{\sqrt{r}}{2}\right) \quad (14)$$

Note that we have absorbed all the remaining terms, including those proportional to $C(\Lambda)$ and $\chi(\Lambda)$ not enhanced by large logarithms, into $\tilde{C}$.

The logarithmically enhanced hadronic light-by-light contributions to a_μ are renormalization scheme-independent. However, the values of $\chi(\Lambda)$, $f(r)$, and the constant appearing in the renormalization group equation for C (leading to the factor of $1/2$ in the $\ln$ term in Eq. (13)) depend on one's choice of scheme³. This scheme-dependence cancels in the sum of their contributions to $a_\mu^{LL}(\text{had})$. For our calculations, we adopted a scheme in which the loop integrals were evaluated in d -dimensions with $d > 4$ (corresponding to $\epsilon < 0$), while the Dirac matrices and photon polarization indices were taken as four-dimensional. For this choice we have $\eta_{\mu\nu}\text{Tr}(\gamma^\mu\gamma^\nu) = 16$ instead of $4d$. Moreover, the value of $\chi(\Lambda)$ in this scheme is the same as that in [14] but is four less than the $\chi(\Lambda)$ used in [17]. An alternative, equally convenient scheme is again to treat the Dirac matrices, epsilon tensors, and photon polarizations as four dimensional; take $d < 4$ ($\epsilon > 0$); and rewrite (3) as

$$i \frac{N_C \alpha^2}{48\pi^2 F_\pi} \frac{(\chi_1 + \chi_2)}{6} \epsilon^{\mu\alpha\nu\lambda} \bar{\mu} \gamma_\mu \gamma_\beta \gamma_\mu \mu \eta_\alpha^\beta \partial_\lambda \left(\pi^0 + \frac{1}{\sqrt{3}} \eta \right) + \dots \quad (15)$$

where the metric tensor $\eta_{\alpha\beta}$ is d -dimensional. In this scheme the value of $\chi(\Lambda)$ is still the same as in [14], but $f(r) \rightarrow f(r) + 3/2$ and the -3 in the renormalization group equation for C becomes -12 . Notice that the total value for the logarithmically enhanced contribution to $a_\mu^{LL}(\text{had})$ is unchanged.

²Since we only compute the terms enhanced by large logarithms to get f we replace $\chi(\mu)$ by $12\ln(\Lambda/\mu)$.

³We will discuss the issue of scheme dependence and give more details of the calculation in a future publication.

As a check on the result in Eq. (13), one may compute the one- and two-loop amplitudes with the insertion of $\chi(\Lambda)$ in Fig. 1b and $C(\Lambda)$ in Fig. 1c. In this case, all of the large logarithms arise from the Feynman amplitudes and not from the operator coefficients. Using an explicit calculation, we have verified in the limit $m_\pi \rightarrow 0$ that this procedure exactly reproduces the expression in Eq. (13). We note that the $\ln^2$ term and the term proportional to χ agree with the expression in Ref. [4].

Chiral perturbation theory can be used for the $\eta \rightarrow \mu^+\mu^-$ amplitude [14], and the LEC $\chi(\Lambda)$ can be deduced from the measured $\eta \rightarrow \mu^+\mu^-$ branching ratio [16]. This yields [17] $\chi(1\text{GeV}) = -14_{-5}^{+4}$ or -39_{-4}^{+5} , where we have scaled the results in Ref. [17] from $\Lambda = m_\rho$ up to $\Lambda = 1\text{ GeV}$ and subtracted four. Note that because the $\eta \rightarrow \mu^+\mu^-$ branching ratio is a quadratic function of χ , two different values for this LEC may be extracted from experiment.

Our calculation of the logarithmically enhanced contributions to $a_\mu^{LL}(\text{had})$ only involved the use of chiral $SU(2)_L \times SU(2)_R$ while this extraction of the LEC involves the use of chiral $SU(3)_L \times SU(3)_R$. Since one expects chiral perturbation theory to work better in the case where only the pions are treated as light it is desirable to have an extraction of χ that only relies on chiral $SU(2)_L \times SU(2)_R$. This can be done using the measured $\pi^0 \rightarrow e^+e^-$ branching ratio which yields [17] $\chi(1\text{GeV}) = -29_{-16}^{+25}$ or $+74_{-25}^{+16}$. Unfortunately, the errors on the extracted $\chi(1\text{GeV})$ are very large in this case. A more precise determination of the $\pi^0 \rightarrow e^+e^-$ branching ratio could reduce the theoretical uncertainty in $\chi(1\text{GeV})$.

Model calculations for $a_\mu^{LL}(\text{had})$ differ from our analysis typically through insertion of form factors at the $P\gamma^*\gamma^*$ vertices obtained from the WZW interaction in Eq. (1). For example, one widely-followed model employs form factors based on a vector meson dominance picture. This approach – known as resonance saturation – may also be used to obtain χ , giving [17] $\chi(1\text{GeV})_{\text{res sat}} \simeq -17$. In a similar vein, one may analyze this LEC at leading order in N_C , where it depends on a sum over an infinite tower of vector meson resonances [18]. Using a model-dependent form factor for the sum over vector resonances that at short distances is consistent with the properties of QCD gives $\chi(1\text{GeV})_{N_C, \text{res sat}} = -16 \pm 5$. This result provides some quantitative support for phenomenological models since it is close to the value $\chi(1\text{GeV}) \simeq -14$ obtained from experiment. However, one would not want to draw conclusions about the validity of the Standard Model using such a model-dependent approach.

Using $\chi(1\text{GeV}) = -14_{-5}^{+4}$ as input, setting $\mu = m_\mu$, and adding the large $\ln^2$ and $\ln$ terms in Eq. (13), we obtain

$$a_\mu^{LL}(\text{had})_{\log} = (57_{-60}^{+50}) \times 10^{-11} \quad . \quad (16)$$

We emphasize that inclusion of *both* the $-f(r) + 1/2$ and $\chi/6$ parts of the $\ln(\Lambda/\mu)$ term is crucial to obtaining an accurate numerical result for $a_\mu^{LL}(\text{had})_{\log}$. If, for example, one were to keep only the dependence on $\chi(\Lambda)$, one would find substantial cancelations between the $\ln^2$ and $\ln$ contributions. The presence of the calculable $-f(r) + 1/2$ term, however, substantially mitigates these cancelations.

We observe that the central value in Eq. (16) is roughly a factor of two larger than obtained in model calculations for the π^0 contribution, and that the uncertainty is about a third the size of the present experimental error in a_μ [1]. After the full E821 data set is analyzed, the uncertainty in Eq. (16) will be comparable to the anticipated experimental error. As noted above, improved measurements of the $\pi^0 \rightarrow e^+e^-$ branching ratio could

reduce the theoretical uncertainty in the large logarithmic contributions to $a_\mu^{LL}(\text{had})$. Using the other value of χ obtained from the $\eta \rightarrow \mu^+\mu^-$ branching ratio, $\chi(1\text{GeV}) = -39_{-4}^{+5}$, leads to $a_\mu^{LL}(\text{had})_{\text{log}} = (-190_{-50}^{+60}) \times 10^{-11}$. Although there exists a strong theoretical prejudice in favor of the first solution [Eq. (16)] based on both the resonance saturation model for χ and $a_\mu^{LL}(\text{had})$ as well as consistency between the values of χ obtained from the $\eta \rightarrow \mu^+\mu^-$ and $\pi^0 \rightarrow e^+e^-$ branching ratios, one cannot rule out the second value for $a_\mu^{LL}(\text{had})_{\text{log}}$.

Adding in the $O(N_C^0\alpha^3)$ charged pion loop contribution [5,15], $a_\mu^{LL}(\text{had})_{\text{l.o.}} = -44.6 \times 10^{-11}$, to that in Eq. (16) gives the following χ PT expression for $a_\mu^{LL}(\text{had})$,

$$a_\mu^{LL}(\text{had}) = (13_{-60}^{+50} + 31\tilde{C}) \times 10^{-11} . \quad (17)$$

The largest uncertainty in the expression for $a_\mu^{LL}(\text{had})$ above arises from the subdominant terms that have not been calculated and are parameterized by the LEC $\tilde{C}$. As noted above, this constant includes the effects of non-logarithmically enhanced two-loop contributions, heavy mesons such as the η and η' which have been integrated out, and other non-perturbative dynamics. On general grounds, one could expect its natural size to be of order unity. A comparison of Eq.(17) with the results of model calculations is consistent with this expectation. For example, the model calculation of Ref. [11] corresponds roughly to $\tilde{C} \simeq 1$. Rigorously speaking, however, the precise value – as well as the sign – of $\tilde{C}$ is unknown. An uncertainty $\Delta\tilde{C} = \pm 1$ corresponds to $\Delta a_\mu^{LL}(\text{had}) = \pm 31 \times 10^{-11}$, which is roughly one fifth of a standard deviation for the published Brookhaven measurement [1]. One should not, however, treat this as an estimate of the theoretical uncertainty in $a_\mu^{LL}(\text{had})$. A value of $\tilde{C}$ equal to +3 or -3, for example, would not be unusual.

Alternatively, one may use the experimental result for a_μ to determine $\tilde{C}$. To that end, we use the up-dated results for hadronic vacuum polarization contributions [2], the QED and electroweak loop contributions in Ref. [19] and the value for $a_\mu^{LL}(\text{had})_{\text{chiral}}$ given in Eq. (17). From the E821 result for a_μ we obtain

$$\tilde{C} = 7 \pm 5 \pm 3 \pm 2 , \quad (18)$$

where the first uncertainty arises from the experimental error in a_μ , the second corresponds to the theoretical QED, electroweak, and hadronic vacuum polarization errors, and the final uncertainty arises from the error in χ . In the future, the first uncertainty will be considerably reduced upon complete analysis of the full E821 data set. The value of $\tilde{C}$ is consistent with unity, though it could be considerably larger, given the other experimental and theoretical inputs into Eq. (18). Using the second solution for χ and $a_\mu^{LL}(\text{had})$ gives $\tilde{C} = 16 \pm 5 \pm 3 \pm 2$.

At present there is no indication that the hadronic LEC $\tilde{C}$ differs substantially from its natural size and, thus, no reason to discern effects of new physics, such as loops containing supersymmetric particles [19], from the a_μ result. In principle, a systematic calculation of some of the effects arising at higher order – such as terms of $O(\alpha^3 N_C^0 p^2/\Lambda^2)$ enhanced by large logarithms – could modify this conclusion [20]. Similarly, should the full E821 data imply a value for $\tilde{C}$ which differs significantly from ± 1 (*e.g.*, by an order of magnitude), one might argue that there is evidence of new physics. Such a conclusion would presumably require considerable disagreement between the published E821 result [1] and the analysis of the full data set. The most convincing analysis, however, would rely on a first principles QCD calculation of $a_\mu^{LL}(\text{had})$, a prospect which seems to lie well into the future.

We thank M. Knecht, A. Nyffeler, M. Perrottet, and E. de Rafael, for pointing out terms omitted in a previous version of the manuscript. We also thank D. Hertzog, A. Kurylov, and W. Marciano for useful discussions.
